Received 19 November 2003; revised 5 February 2004; accepted 1 March 2004; published 2 April 2004.

[1] U/Th dating and oxygen isotope analysis of a stalagmite from Spannagel Cave in the Austrian Alps provides information about the timing and progression of the last interglacial climate. We determined two distinct growth intervals (warm climate) from ~ 130.7 thousand years (ka) before the present to 130.0 ka and from ~ 125.7 ka to 118.2 ka, the latter containing two periods of ceased stalagmite growth (colder climate) at around 123.8 ka and 120.5 ka. High resolution $\delta^{18}\text{O}$ analysis of stalagmite SPA 50 reveals a clear regular cyclic pattern with periods of 197, 109, and 21 years, which are likely to be related to the Suess, Gleissberg, and Hale cycles respectively, indicating that Eemian climate in the Alps was forced by the Sun. **INDEX TERMS:** 1035 Geochemistry: Geochronology; 1040 Geochemistry: Isotopic composition/chemistry; 3344 Meteorology and Atmospheric Dynamics: Paleoclimatology; 7536 Solar Physics, Astrophysics, and Astronomy: Solar activity cycle (2162). **Citation:** Holzkämper, S., A. 1. Introduction

[2] The timing and duration of the Eemian interglacial climate has been extensively discussed [e.g., Shackleton *et al.*, 2002]. According to the Milankovitch insolation curve, Marine Isotope Stage 5 (MIS 5) does not commence before 128 ka. In contrast, both marine and terrestrial datasets define the beginning of the Last Interglacial between 135 ka and 140 ka [Gallup *et al.*, 2002; Henderson and Slowey, 2000; Spötl *et al.*, 2002; Winograd *et al.*, 1992]. The stability of the Eemian climate has been discussed controversially [Boettger *et al.*, 2000; Frogley *et al.*, 1999; Fronval and Jansen, 1996; Hearty and Neumann, 2001; Rioual *et al.*, 2001]. Resolving these issues will lead to an improved theory of glacial-interglacial transitions. One major setback results from the lack of reliable absolute age determinations. Speleothems offer an important but yet underutilized source of information about the timing and progression of the Last Interglacial.

2. Geological and Climatic Setting

[3] An ideal situation for paleoclimatic reconstruction would entail speleothem growth itself being an indicator of

warm climate, as is the case in Spannagel Cave, located in the Austrian Alps, at an altitude of 2,500 m above sea level. At present the area above Spannagel Cave is ice-free, but was covered by the nearby Hintertux Glacier during glacials [Spötl *et al.*, 2004]. Speleothems in Spannagel are able to grow despite the absence of soil overlying the cave owing to the presence of pyrite in the host rock, which under oxidizing conditions can transform into sulfuric acid. The acid dissolves the primary limestone, producing excess CO_2 , which results in the formation of supersaturated carbonate solutions and calcite precipitation. The interior cave temperature (at present $+1.2$ to $+2.2^\circ\text{C}$, depending on the location within the 10 km cave system) shows no daily or seasonal variation and corresponds closely to the mean annual external air temperature [Spötl *et al.*, 2004]. As speleothems can only develop above freezing point, growth of speleothems in Spannagel Cave is sensitive to temperature shifts.

3. Methods

[4] 22 subsamples along the growth axis of stalagmite SPA 50 were taken for U/Th age determination. U/Th measurements were performed on a thermal ionization mass spectrometer (Finnigan MAT 262 RPQ) with a double filament technique¹. The detrital correction was performed using a factor of 3.8 [Wedepohl, 1995] for the mass ratio of ^{232}Th and ^{238}U in the detritus. The correction led to negligible age changes (<0.024 ka) owing to low ^{232}Th concentration. All ages were calculated using half lives for ^{230}Th of 75,381 years, for ^{234}U of 244,600 years, and for ^{238}U of 4.4683×10^9 years [Cheng *et al.*, 2000]. Age errors do not include half-life uncertainties. The reproducibility of the $^{233}\text{U}/^{236}\text{U}$ double spike is 1‰ and that of the ^{230}Th spike is 2‰. Samples for stable oxygen isotope analysis were micromilled in 150- μm intervals and measured using an on-line, automated carbonate preparation system linked to a triple collector gas source mass spectrometer. Values are reported relative to Vienna Pee Dee Belemnite standard. The precision of the $\delta^{18}\text{O}$ values (1σ standard deviation of replicate analyses) is 0.075‰ [Spötl and Vennemann, 2003].

4. Speleothem Growth Periods

[5] The previously studied flowstone SPA 52 [Spötl *et al.*, 2002] grew during MIS 7 and MIS 5. The beginning of the Last Interglacial was dated at 135.0 ± 1.2 ka (all errors reported are 2σ), and the Eemian lasted until 116.0 ± 1.9 ka. There are no indications of post-depositional U-leaching processes (such as deviations in $\delta^{234}\text{U}$ or macroscopic pores), nor is it likely that older carbonate from MIS 7 section has

Figure 1. $\delta^{18}\text{O}$ profile of stalagmite SPA 50 and U-series ages with 2σ errors. The vertical line indicates the position of hiatus H3 separating growth units U3 and U4. Growth unit U4 is subdivided into three subunits, U4a, U4b, and U4c, by two steps in the depth age profile at about 97 mm and 246 mm from the stalagmite base (vertical dotted lines). Also shown are the calculated (solid lines) and estimated (dotted lines) age models for each growth section.

influenced the 135 ka sample, with the respective hiatus being 11 mm below the spot the sample was taken from, so that the early start of the Last Interglacial is regarded as reliable. An unconformity within the MIS 5e section of the flowstone indicates a cessation of calcite deposition between 129.2 ± 1.8 and 121.8 ± 0.9 ka, separating the two growth units U3 and U4. This boundary was denoted as H3 in SPA 52 [Spötl *et al.*, 2002]. The growth intervals indicate periods with temperatures that were similar or slightly higher than today's, allowing for speleothems to form in this high-altitude cave setting. As the MIS 5e interval in SPA 52 is represented by a section of only 82 mm thickness, the resolution of the record is comparably poor. Here we present results from the 252 mm long stalagmite SPA 50, which grew in the same cave chamber only a few meters away from flowstone SPA 52 and was found lying on the cave floor detached from its substrate. Due to the higher growth rate of SPA 50 we were able to obtain a record which has a temporal resolution that is about three times higher than that of SPA 52. It is characterized by a macroscopic hiatus about 25 mm above its base separating the lower section with ^{238}U concentrations of about 70 ppm, denoted as U3, from the middle and upper sections with about 3.5 to 8.5 ppm, labeled U4 (similar concentrations were found in the respective sections of flowstone SPA 52). The lowermost 25 mm have a significantly higher ^{232}Th concentration of about 20 ppb than the main section of the stalagmite (1 to 5 ppb), which is still too low to indicate an influence on the age determinations by detrital contamination.

[6] The first depositional phase of SPA 50 (U3) yielded ages of 130.5 ± 1.1 ka and 130.2 ± 1.2 ka (Figure 1). Thus, the growth of stalagmite SPA 50 commenced about 4.5 ka later than that of flowstone SPA 52. Whilst stalagmite growth requires water seepage from the ceiling, the presence of water on the ground is sufficient for flowstone growth. The offset in growth initiation therefore indicates that water on the ground of this cave chamber was present prior to ceiling water seepage. The subsequent growth cessation is marked by a macroscopic hiatus and a step in the age-depth profile and

may be associated with a Younger Dryas-like cold spell occurring after a first warming of the Last Interglacial. Its existence has also been recorded in other climate archives [Esat *et al.*, 1999; Sanchez Goni *et al.*, 1999]. It might have been caused by freshwater pulses to the North Atlantic, reducing the formation of North Atlantic Deep Water and thus the heat transport to Northern Europe [Clark *et al.*, 2001], as in the Younger Dryas, which also occurred within a period of maximum solar summer insolation. After the growth cessation, calcite deposition recommenced at 125.6 ± 0.9 ka (U4). The youngest available date for this growth phase was obtained at 118.2 ± 0.6 ka. One point with an age of 128.3 ± 1.3 ka from SPA 50 is interpreted as a mixing age due to the short distance from the hiatus and therefore was excluded from the following interpretation. U4 in stalagmite SPA 50 is represented by 19 dated points and shows two distinct jumps towards younger U/Th ages at around 123.8 ka and 120.5 ka, subdividing U4 into three subunits U4a, U4b, and U4c. Ages obtained from the upper section of the adjacent flowstone sample SPA 52 [Spötl *et al.*, 2002] scatter around the values within U4b and U4c of SPA 50. In SPA 52, the two respective growth reductions are not visible, probably due to the lower temporal resolution in comparison to SPA 50. However, the youngest age of the Last Interglacial is recorded more reliably by SPA 52 at 116.0 ± 1.9 ka, because the uppermost part of stalagmite SPA 50 has a lower temporal resolution.

[7] Provided that the growth interruptions centered at around 123.8 ka and 120.5 ka recorded by the U/Th dates of SPA 50 are not the product of incidentally changed flowpaths of the drip waters, they are likely to represent cold spells when mean annual temperatures were at least 1° to 2°C lower than today. The duration of the interruptions cannot be determined precisely due to the dating uncertainty, but is in the order of 1 to 2 ka. A number of climate archives from various locations also show the existence of cooler, but not glacial periods at ~ 124 ka [Hearty and Neumann, 2001; Wilson *et al.*, 1998] and at ~ 121 ka [Linsley, 1996; Stirling *et al.*, 1998].

5. Oxygen Isotope Record

[8] In Figure 2 we show the growth periods and isotopic age profile of SPA 50. The age models for growth periods

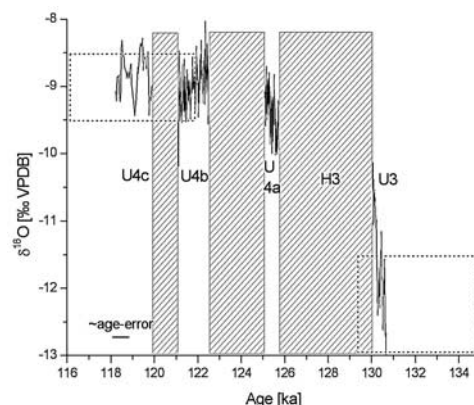

Figure 2. $\delta^{18}\text{O}$ profile of stalagmite SPA 50 versus age derived from the dates shown in Figure 1. The shaded boxes mark periods of ceased stalagmite growth. The two dashed boxes indicate the growth periods and $\delta^{18}\text{O}$ range of flowstone SPA 52.

U3 and U4b are based on linear, error-weighted fits through the dated points, entailing growth rates of 48 mm/ka (U3) and 107 mm/ka (U4b), respectively. For U4a, the same growth rate as for U4b was assumed, owing to the broadly scattered ages of U4a, where a fit function would yield a negative growth rate. The growth rate of the youngest section of the stalagmite, U4c, was calculated by defining the two determined ages as the endpoints of the growth period U4c, resulting in a growth rate of 5.4 mm/ka, and not by extrapolating the growth rate to the end of the respective section, as it was performed in all the other growth phases; it therefore provides only a rough estimate.

[9] During growth phase U3 $\delta^{18}\text{O}$ values in both samples range between -13.0‰ and -11.0‰ , except for the older part of SPA 52 with fluctuations from -10.7‰ to -14‰ . The beginning of U4 is marked by a significant increase of $\delta^{18}\text{O}$ to values of around -9.5‰ in both samples. It has been argued earlier that the difference of 2‰ to 3‰ in $\delta^{18}\text{O}$ between sections U3 and U4 may not convincingly be explained by a temperature increase and is more likely to reflect a change in water sources [Spötl *et al.*, 2002]. This means that the more negative isotopic values in U3 reflect a larger contribution of melt waters from the nearby glacier. The glacier retreat led to a stronger influence of precipitation on drip waters in the cave, leading to heavier $\delta^{18}\text{O}$ values.

[10] The $\delta^{18}\text{O}$ values of U4 correspond roughly with those of Holocene speleothems from Spannagel Cave, showing values around -7.8‰ , in equilibrium with $\delta^{18}\text{O}$ of precipitation [Spötl *et al.*, 2004]. The difference of about 1‰ to 2‰ in comparison to recent calcite would result in temperatures 4° to 8°C higher than today [Friedman *et al.*, 1977]. However, this difference may not solely be explained by temperature. Instead it may be ascribed to more negative $\delta^{18}\text{O}$ values of precipitation or to a larger contribution of melt waters from the nearby glacier in comparison to the Holocene.

[11] During the Eemian, the profile of $\delta^{18}\text{O}$ in U4a of SPA 50 increased from -9.7‰ to -9.1‰ and in U4b the $\delta^{18}\text{O}$ values show a slight downward trend from -8.8‰ to -9.2‰ . The boundary between U4b and U4c is marked by a negative spike in $\delta^{18}\text{O}$ down to -10.3‰ , which may indicate a relapse to colder conditions with an increased contribution of glacial melt water in the cave. High amplitude variations of 1‰ mark the uppermost part (U4c) before the growth ceased. Presuming that $\delta^{18}\text{O}$ precipitation values remained constant during the Eemian, we can deduce from the 0.9‰ difference in $\delta^{18}\text{O}$ values that variations in the range of 4°C occurred, with higher temperatures at the beginning (U4a) of this period.

[12] The short term variations in $\delta^{18}\text{O}$ of $\pm 0.5\text{‰}$ in sections U4a, U4b, and U4c of stalagmite SPA 50 probably reflect both the fluctuations in temperature inside the cave, influencing the fractionation coefficient of calcite precipitation, as well as variations in the $\delta^{18}\text{O}$ precipitation values. These may have been caused by any combination of the following factors: temperature, amount effect, changed seasonality of rainfall or alterations in storm and cloud tracks in the Central Alps. This latter effect has been investigated earlier [Florineth and Schlichter, 2000], where it has been assumed that during colder periods the prevailing westerly circulation pattern over Central Europe was displaced by an enhanced southerly wind component from the Mediterranean. From our data it is not possible to

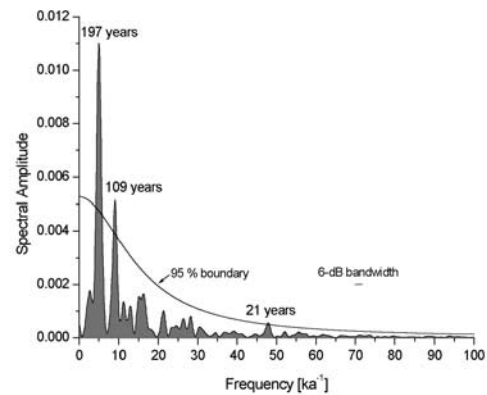

Figure 3. Spectral analysis for the high resolution interval U4b [Schulz and Mudelsee, 2002]. Spectral amplitude was estimated using the Lomb-Scargle Fourier Transform for unevenly spaced data, a Welch I window and two overlapping (50%) segments; red-noise boundary was estimated as upper 95% chi-squared limit of a fitted AR1 process. High time-resolution and uneven spacing prohibit effectively against aliasing effects [Priestley, 1981]. The 6-dB bandwidth (frequency resolution) is 1.77 ka^{-1} .

deduce exact temperature shifts from the stable isotope variations nor to determine the quantitative contributions of the above mentioned processes. Additional investigations, such as fluid inclusion analyses and modeling of stable isotopes in precipitation will help to quantify the relative influences of the suggested processes.

6. Spectral Analysis

[13] In comparison to other Eemian climate records the uniquely high resolution of the $\delta^{18}\text{O}$ profile in the growth interval U4b from SPA 50 allows to decipher hidden periodicities within the time series using spectral analysis (Figure 3). Three spectral peaks at 197, 109, and 21 years period, clearly exceed the 95% confidence bound. Considering the frequency resolution (6-dB bandwidth) and the additional uncertainty of the used age model, these peaks might well correspond to the Suess cycle (206 years period), Gleissberg cycle (89 years), and Hale cycle (22 years), which are well established solar signals found in climate archives over Holocene periods [Hoyt and Schatten, 1997; Stuiver and Braziunas, 1993].

[14] In the Holocene, North Atlantic marine sediments reveal a strong correlation between solar induced ^{10}Be and ^{14}C fluctuations and variations in surface winds and surface ocean hydrography on centennial to millennial timescales [Bond *et al.*, 2001]. Two Holocene stalagmites from Sauerland, Central Germany, support the finding of a teleconnection between solar activity and climate in Central Europe: the $\delta^{18}\text{O}$ records of stalagmites B7-7 and AH1 show a strong correlation with the solar induced $\delta^{14}\text{C}$ [Niggemann *et al.*, 2002, 2003]. As the climate of Central Europe is predominantly influenced by the North Atlantic, our high-resolution record SPA 50 suggests that solar activity modulated the high alpine climate during the Eemian on decadal to centennial timescales in a similar fashion. The mechanism linking solar output variations to tropospheric

climate oscillations is still uncertain. One possibility is that variations in the intensity of galactic cosmic rays in the atmosphere cause changes in cloudiness. Another mechanism suggests that UV irradiance variations affect ozone, which changes the temperature and wind pattern in the stratosphere, in turn altering tropospheric climate [Carslaw et al., 2002; Rind, 2002].

7. Conclusions

[15] Our high-resolution study of speleothems from the Central Alps reveals a warm phase prior to the classical Eemian from ~ 135 to 130 ka. The ambient temperature during the Eemian, from 125.7 ± 0.9 ka to 116.0 ± 1.9 ka, was at least as high as today in this region. This dataset provides a precise time frame for other continental climate archives for the duration of the Eemian. The growth reductions of stalagmite SPA 50 at about 123.8 ka and 120.5 ka could be the product of cold spells, during which the annual mean temperature was at least 1° to 2°C lower than today. Spectral analysis reveals solar forcing of the Eemian climate.
